Abstract. Context. We investigate mid-infrared and X-ray properties of the dusty torus in unification scenarios for active galactic nuclei.

Aims. We use the relation between mid IR and hard X-ray luminosities to constrain AGN unification scenarios.

Methods. With VISIR at the VLT, we have obtained the currently highest angular resolution (0.15 FWHM) narrow-band mid infrared images of the nuclei of 8 nearby Seyfert galaxies. Combining these observations with X-ray data from the literature we study the correlation between their mid IR and hard X-ray luminosities.

Results. We find that the rest frame 12.3 μm (LMIR) and 2-10 keV (LX) luminosities are correlated at a highly significant level. The best fit power-law to our data is log L_{MIR} \propto (1.60 \pm 0.22) log L_X, showing a much smaller dispersion than earlier studies.

Conclusions. The similarity in the log L_{MIR}/log L_X ratio between Sy1s and Sy2s even using high angular resolution MIR data implies that the similarity is intrinsic to AGN and not caused by contamination from extra-nuclear emission. This supports clumpy torus models. The exponent of the correlation constrains the inner geometry of the torus.

Key words. galaxies: active – Infrared: galaxies – X-rays: galaxies

1. Introduction

The unification model for active galactic nuclei (AGN) interprets the different appearance of Seyfert 1 (Sy1) and Seyfert 2 (Sy2) galaxies uniquely as the result of an orientation effect (Antonucci 1993; Barthel 1994; Urry & Padovani 1996). The central engine is considered to be surrounded by an optically and geometrically thick molecular torus. Associated with this torus are large masses of dust that supposedly reprocess the X-ray and UV emission from the accretion disk and re-emit it in the mid infrared (MIR) regime (Pier & Krolik 1993).

It is thus very attractive to search for correlations between IR continuum and hard X-ray emission in order to test the unification scenarios for AGN. A tight correlation between the 10.5 μm continuum and the absorption-corrected 2-10 keV luminosities for 8 nearby Seyfert galaxies was reported by Krabbe et al. (2001) using 1″2 resolution MIR data. More recently Lutz et al. (2004) found a correlation between the rest frame 6 μm luminosity and the absorption-corrected hard X-ray luminosity for a sample of 71 AGN. This sample was comprised of objects for which 24″ angular resolution ISO PHOT spectra and hard X-ray observations were available; in particular it does not contain Compton-thick objects. However, the authors reported two problems that the unification model faces when compared with their observations. (I) The scatter of the relation is about an order of magnitude larger than expected from the results of Krabbe et al. (2001). (II) There is no significant difference between early type (Sy types 1 to 1.5) and late type (Sy types 1.8 to 2) objects in the average ratio of mid-infrared to hard X-ray emission, as would be expected from an optically and geometrically thick torus dominating the mid-IR AGN continuum.

Here we study this relation through rest wavelength 12.3 μm photometry of AGN, improving upon Krabbe et al. (2001) and Lutz et al. (2004) by a factor of 3 and 80, respectively, in terms of angular resolution. The wavelength was chosen as, among the bands accessible from the ground, it best traces hot and warm dust.

Throughout this paper we assume H_0 = 72 km/s, Ω_Λ = 0.73 and Ω_m = 0.27 (Spergel et al. 2003).

2. Observations and data analysis

Between March and July 2005 we observed 8 nearby Seyfert nuclei (see Table 1), selected from the sample used by Lutz et al. (2004), with VISIR (Lagage et al. 2004) at the VLT. The individual objects were selected as to avoid a strong bias toward higher luminosities with higher redshift. All observa-
tions were carried out under good photometric and optical seeing conditions (≤ 0.8′′) and with airmass below 1.3. For all observations we used the parallel chop/nod mode of VISIR with a chopping throw of 8′′, thus receiving all three beams on the detector. We observed each object in three different narrow-band filters in order to obtain the rough shape of its MIR spectral energy distribution (SED). These filters were chosen as to avoid emission and absorption lines, in particular the 12.8 µm NeII line and the broad 9.7 µm silicate feature which in cases of very strong absorption can extend to λ ≃ 12.5 µm. NGC 7314 was only observed in two different filters. Total integration times ranged between 1.2 and 9.2 min per filter and per object.

We reduced science and standard star frames using the pipeline written by Eric Pantin (private communication). To eliminate glitches, the pipeline applies a bad pixel mask and removes detector stripes. Subsequently we removed background variations using a 2 dimensional polynomial fit. Here we treated each nodding cycle separately as the background pattern sometimes changes between two consecutive cycles. The count rate for one full exposure was calculated as the mean of all 3 beams from all nodding cycles of this exposure. As an error estimate we use the standard deviation of these. In order to minimise the effect of residual sky background we chose relatively small apertures (∼ 10 pixels = 1′′.27) for the photometry and corrected the obtained count rates using the radial profiles of standard stars. Finally we calibrated our photometry using the same standard stars. These were observed within 1.5 hrs of the science exposures and with a maximum airmass difference of 0.15. Our observational results are shown in Table 2. Comparing the FWHM of standard star and science exposures yields no indication that our sources are extended. Thus our observations indeed probe the physical scales given in Table 1.

3. Results

Figure 1 shows all photometric data points taken during our observing programme. For comparison Fig. 2 shows our measurements together with ISOPHOT spectra taken from Risopoulou et al. (1999) for these three sources common to both samples. Among our data the SED of PKS 2048-57 is the only one displaying a strong 9.7 µm silicate feature which, however, does not significantly affect our measurement of the continuum flux in the NeIIref1 filter. This is important as it validates our result on the MIR − hard X-ray correlation (see below).

One of the objects in our sample – NGC 4579 – has peculiar MIR properties. Comparing the ISOPHOT 6 µm flux reported in Lutz et al. (2004) of S<sub>6µm</sub> = 96 mJy to our VISIR flux levels (see Table 2) leads to the conclusion that either this object has a peculiar MIR SED that does not rise toward longer wavelengths as expected for typical AGN or that the bulk of IR emission (≥ 70%) does not originate in the central point source. In both cases it is highly questionable whether the latter is dominated by a molecular torus. Moreover, Contini (2004) reports the MIR emission of NGC 4579 to be dominated by thermal emission of shock-heated ISM in the vicinity of the nuclear region rather than by reprocessed X-ray and UV emission from the central engine itself. These peculiarities plus the fact that NGC 4579 has also been classified as a low-ionisation nuclear emission region (LINER) by Keel (1983) and Filippenko & Sargent (1985) led us to exclude it from the MIR − hard X-ray correlation investigated here. NGC 7314, the other low luminosity object in our sample, harbours a regular Seyfert nucleus (Lumsden et al. 2004).

For all objects in our sample we calculated the 12.3 µm rest frame luminosity by using the filter with the central wavelength closest to 12.3 µm and assuming a flat SED in this spectral region. Then we compiled absorption-corrected 2-10 keV measurements for our sample from the literature (see Table 1 for details). When several such measurements were available we use the mean luminosity for the MIR − hard X-ray correlation and take half of the peak-to-peak variability as a conservative estimate of the uncertainty in the hard X-ray luminosity. Only one such measurement could be found for PG 2130+099 for which we therefore assumed a variability of a factor of 2. As we derive the luminosity distances of all targets solely from their redshifts we assume an uncertainty of 3 Mpc due to possible deviations from the Hubble flow. This is applied to the error bars of both X-ray and MIR luminosities.

The resulting MIR − hard X-ray correlation we obtain for our VISIR sample is shown in Fig. 3. Pearson’s coefficient is r = 0.98 meaning that the correlation is highly significant. The
Table 2. Basic observational parameters for all data used: Object name, observing date (in 2005), filter, flux and full width half maximum for standard star (STD) and science observations. As error estimates we use the standard deviation of all contributing beams (see section 2 for details). The FWHM are the average of all beams of one exposure. All science and corresponding STD exposures were obtained within a maximum airmass difference of 0.15. ∗ The central wavelengths for the individual filters are $9.82\,\mu m$ for SIVref1, $10.49\,\mu m$ for SIV, $11.25\,\mu m$ for PAH, $11.88\,\mu m$ for PAH2ref2, $12.27\,\mu m$ for NeIIref1 and $12.81\,\mu m$ for NeII. Their transmission curves are shown in the VISIR User’s manual at http://www.eso.org/instruments/visir.

Fig. 1. The MIR SEDs of our sample of galaxies. Early- and late-type Seyferts are shown in the left- and right-hand panel respectively. Horizontal error bars show the band width of the used filters. The flux densities of NGC 7314 have been offset by $+1 \cdot 10^{-10}\,\text{erg s}^{-1}\,\text{cm}^{-2}$ for clarity.

Fig. 2. Comparison of ISOPHOT-S spectra (dashed histograms) taken from Rigopoulou et al. (1999) and our VISIR photometry (filled circles). Horizontal error bars show the band width of the filters used.

best fit power-law to our data is $L_{\text{MIR}} = (-25.4 \pm 9.5) + (1.60 \pm 0.22) \cdot \log L_X$ with measurement errors considered in the fit. Including NGC 4579 into the fit yields an exponent of $\sim 1.28$ rather than $1.6$ and $r = 0.95$.

4. Discussion and conclusions

We have presented new high-resolution MIR observations of 8 nearby Seyferts, obtained with VISIR at the VLT. We found that their rest-frame $12.3\,\mu m$ and absorption-corrected 2-10 keV luminosities are strongly correlated following $L_{\text{MIR}} \propto L_X^{1.6}$. Early- and late-type Seyfert galaxies follow the same relation. At the low-luminosity end the correlation is not well defined.
as one of the two object’s MIR radiation is very probably not
dominated by a dusty torus.

Both Krabbe et al. (2001) and Lutz et al. (2004) found a
correlation close to $L_{\text{MIR}} \propto L_X^{1.5}$. The exponent different to the one we find is most probably due to the difference in angular
resolution ($24''$ for ISOPHOT, 1.2'' for Krabbe et al.’s sample
and $\approx 0.35''$ for VISIR) and to the choice of the rest frame
wavelength as the intervening medium is expected to be more
optically thin at $12.3\mu m$ than at shorter wavelengths. In
particular, using the corresponding ISOPHOT $6\mu m$ data for our
sample also yields an exponent close to 1. In addition we find a
dispersion similar to the one in Krabbe et al. (2001); the larger
one reported by Lutz et al. (2004) can be attributed to their
relatively poor angular resolution and the fact that the emission
at $6\mu m$ is slightly more dependent on inclination effects
(e.g. see Hönig et al. 2004). On the other hand we confirm the
absence of a significant difference in the $L_{\text{MIR}} / L_X$ ratio
between early and late-type objects found by both other studies.
At our high angular resolution this is clearly in disagreement
with smooth torus models, in which a flux difference of one
order of magnitude is expected for type 1 and type 2 AGN
of the same bolometric luminosity (e.g. Pier & Krolik 1993).
This cannot be accounted for by dust clumps situated in the
ionisation cone (Efstathiou et al. 1995) because their contribution
to the nuclear MIR flux should not exceed 50% (see Galliano et al. 2005). Clumpy torus models (e.g. Nenkova et al. 2002) do not predict such an offset and seem to be compatible with our results.

Hönig et al. (2006) recently used 3D radiative transfer
modelling to demonstrate that clumpy tori can appear as
optically thin in the MIR with most of the radiation originating
in the innermost part of the torus. In their model individual
clouds are optically thick but their filling factor is very small.
Consequently lines-of-sight to the innermost clouds are
usually not blocked by other clouds. This implies that $L_{\text{MIR}}$
is proportional to the surface area $A$ of the inner edge of the
torus and the covering factor of clouds projected on $A$. Our
finding that Sy1s and Sy2s follow the same $L_X - L_{\text{MIR}}$
relation is a strong indication that the torus appears optically thin
at $12.5\mu m$.

The correlation we find then requires a dependency of $A$
or the covering factor on $L_X$ and thus the bolometric luminosity $L_{\text{Bol}}$. The simplest explanation for this observed effect is flaring: If the torus’ inner edge is defined by the dust sublimation
radius $r_0$, we obtain $A = 2\pi r_0 \cdot H(r_0)$ where $H(r)$ is the
scale height of the cloud distribution. For a flaring disk $H(r)$ can be written as $H(r) \propto r^\alpha$ with $\alpha$ being constant. This
assumption yields $A \propto r_0^{1+\alpha}$. The dust sublimation radius $r_0$
follows $r_0 \propto L_{\text{MIR}}^{0.5} \propto L_X^{0.5}$. This leads to $L_{\text{MIR}} \propto L_X^{1.5+0.5\alpha}$. Our
observations yield $L_{\text{MIR}} \propto L_X^{1.6}$ and thus $\alpha \approx 2$. Including NGC 4579 results in $\alpha \approx 1.5$.

Another possibility is that its scale height depends on
the radial accretion rate $M$. The torus model presented by
Beckert & Duschl (2004) predicts $H(r)/r \propto M^{0.5}$. For AGN
with comparable radiative efficiencies $M$ is proportional to $L_X$. This yields $L_{\text{MIR}} \propto M_X^{1.5}$ which is very close to the correlation
we find.

The high angular resolution of our MIR observations indi-
cates that the similarity of the $L_{\text{MIR}} / L_X$ ratio for Sy1s and
Sy2s is intrinsic rather than caused by extra-nuclear emission.
Although contributions of dust clumps situated in the ionisa-
tion cone cannot be ruled out they should not dominate the
nuclear MIR flux. Assuming our sample is representative of the
general AGN population our results thus support recent
models of clumpy dusty tori (e.g. Nenkova et al. 2002; Hönig et al.
2006) and, furthermore, indicate that the filling factor of clouds
is small. The geometry of the torus can be constrained by the
slope of the $L_X - L_{\text{MIR}}$ correlation. Clumpy tori with low filling
factors might also account for the similarity of Spitzer spectra
of type 1 and type 2 QSOs (Sturm et al. 2006).

Acknowledgements. We thank Thomas Beckert, Sebastian Hönig
and Eric Pantin for helpful discussions and an anonymous referee for com-
ments and suggestions. This research made use of the NASA/IPAC
Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the
National Aeronautics and Space Administration.
